## Summary

ROC curve is a popular graphical method frequently used in order to study the diagnostic capacity of continuous (bio)markers. When the considered outcome is a time-dependent variable, the direct generalization is known as *cumulative/dynamic* ROC curve. For a fixed point of time,  $t$ , one subject is allocated into the *positive* group if the event happens before  $t$  and into the *negative* group if the event is not happened at  $t$ . The presence of *censored* subject, which can not be directly assigned into a group, is the main handicap of this approach. The proposed cumulative/dynamic ROC curve estimator assigns a probability to belong to the negative (positive) group to the subjects censored previously to  $t$ . The performance of the resulting estimator is studied from Monte Carlo simulations. Some real-world applications are reported. Results suggest that the new estimators provide a good approximation to the real cumulative/dynamic ROC curve.

*Key words:* Cumulative/dynamic ROC curve; Censored data; Cox regression model; Sensitivity; Specificity.

## 1. Introduction

The receiver operating-characteristic (ROC) curve [1] is a popular graphical method which, given a diagnostic (bio)marker, displays the false-positive rate (i.e., the inability of the marker to recognize a normal subject, without the studied characteristic, as normal) against the true-positive rate (i.e., the ability of the marker to detect the characteristic of interest, frequently one disease) for all possible thresholds. In addition, the area under the ROC curve (AUC) is frequently used as diagnostic accuracy index. Particularly, in models where the dependent variable is dichotomous, it can be read as a goodness of fit index, for instance, in logistic regression models. In the last decades, both ROC curve and the AUC have received great attention in the specialized literature. There exists a large number of papers which deal with both theoretical and practical aspects of the ROC curve and related problems (see, for instance, Martínez-Cambor [2] for a recent review). The general ROC curve comparison (the manuscripts of Moise, Clement and Raissis [3], Venkatraman and Begg [4], Venkatraman [5], Bandos, Rockette and Gur [6], Braun and Alonzo [7], Martínez-Cambor, Carleos and Corral [8], Krzanowski and Hand [9] and Martínez-Cambor, Carleos and Corral [10] deal with different aspects of this problem from different approaches), ROC curve regression (Cai [11] and Rodríguez-Álvarez et al. [12]), ROC curve for time-dependent events (Heagerty and Zheng [13], Wolf, Schmidt and Ulm [14], among others), meta-analysis of ROC curves (Rutter and Gatsonis [15], Martínez-Cambor [16]) or the study and estimation of its associated cut-off point (Yousef, Kundy and Wagner [17] and Martínez-Cambor [18]) are among the main focuses of interest. Of course, there also exist a number of softwares which perform calculus and figures, just as example, the R package: `pROC`, `ROCR` or `rocplus`, among much others, are freely available in the CRAN ([www.r-project.org](http://www.r-project.org)).

The case where the studied characteristic (disease) is a time-dependent event has also been considered from different approaches. The most direct ROC curve generalization is to reduce the time-dependent event to a dichotomous variable

for each particular fixed moment  $t$ . Hence, assuming, without loss of generality, that larger values of the marker,  $X$ , are associated with higher probabilities of the event, the (cumulative) sensitivity, or true-positive rate, and the (dynamic) specificity, or true-negative rate, are respectively defined by:

$$S_E^C(x, t) = \mathcal{P}\{X > x | T \leq t\}, \quad (1)$$

$$S_P^D(x, t) = \mathcal{P}\{X \leq x | T > t\}, \quad (2)$$

where  $T$  denotes the time variable. The resulting ROC curve, based on the above *cumulative* sensitivity and *dynamic* specificity, is known as *cumulative/dynamic* (C/D) ROC curve [4],  $\mathcal{R}_t^{C/D}(\cdot)$ . In this approach, all subjects will be used at any fixed time  $t$ . The  $i$ -th individual is considered as positive (case) if  $t_i \leq t$ , and as negative (control) if  $t_i > t$ . The cumulative/dynamic ROC curve is appropriate if the predictive model is built by using markers measured at baseline and the researcher is interested in the prognostic properties for a particular (or a small number of) time. With complete information, empirical estimators can be directly defined by,

$$\hat{S}_E^C(x, t) = \#\{x_i > x \wedge t_i \leq t\} / \#\{t_i \leq t\} \quad (3)$$

$$\hat{S}_P^D(x, t) = \#\{x_i \leq x \wedge t_i > t\} / \#\{t_i > t\}. \quad (4)$$

Of course, censored data are the main handicap in order to estimate  $\mathcal{R}_t^{C/D}$ . Subjects failing before  $t$  or with a follow-up longer than  $t$  are directly allocated into the positive and the negative group, respectively. However, it is not clear what to do with those subjects censored before  $t$ ; this is the case of subject D in Figure 1.

Perhaps, in this case, the first temptation is to define an estimator based on the traditional Kaplan-Meier survivor function. However, this estimator, proposed by Heagerty, Lumley and Pepe [19], has serious drawbacks; *i*) it can take values greater than 1, *ii*) it can drive to non-monotone sensitivity or specificity functions. Alternatively, in the same paper, the authors also proposed a  $\mathcal{R}_t^{C/D}$  estimator based on the nearest neighbor estimator (KNN) for bivariate

distributions under random censoring proposed by Akritas [20]; main handicap of this estimator is that the researcher must define a smoothing parameter. Most recently, Wolf, Schmidt and Ulm [14] proposed an estimator based on the Nelson-Aalen cumulative incidence curve (CIC). The use of the Nelson-Aalen estimator avoids the point  $i$ ) but, as the authors recognize, additional procedures, such as isotonic regression, must be used in order to avoid the point  $ii$ ).

Other possible time-dependent generalizations for the sensitivity,  $S_E$ , and the specificity,  $S_P$ , have been proposed (see Cai et al. [21] for a recent approach). Particularly, Heagerty and Zheng [13] considered the *incident* sensitivity defined by Etzioni et al. [22] as

$$S_E^{\mathbb{I}}(x, t) = \mathcal{P}\{X > x | T = t\}$$

to introduce the *incident/dynamic* (I/D) ROC curve,  $\mathcal{R}_t^{\mathbb{I}/\mathbb{D}}(p) = S_E^{\mathbb{I}}([1 - S_P^{\mathbb{D}}]^{-1}(t, p), t)$  ( $0 \leq p \leq 1$ ) where  $[1 - S_P^{\mathbb{D}}]^{-1}(t, p) = \inf\{x : [1 - S_P^{\mathbb{D}}](x, t) \leq p\}$ . From this approach the  $i$ -th subject is considered as control for  $t_i > t$  and plays the role of

## Follow-up

Figure 1: Schematic situation; A and B are allocated in the negative group, C in the positive group while D is not directly assigned.

case when  $t_i = t$ . The I/D ROC curve approach has clear links with the risk functions and, therefore, also with survival hazard models. In addition, the incident sensitivity allows a direct generalization to the case where the considered marker,  $X$ , is also a time-dependent variable ( $= X(t)$ ). However, it is difficult to interpret without the proportional hazard assumption.

In this paper, the authors are concerned with the C/D ROC curve estimation. With this goal, the *undefined subjects* (those censored before  $t$ ) are treated as *mixed subjects*. They are not completely assigned to a group; but the probability of to be or not be in the group is considered. Rest of the paper is organized as following; in section 2 the proposed estimator is described and its performance is evaluated, via Monte Carlo simulations, in section 3. Section 4 is devoted to real application; particularly, the relationship between the forced ventilatory volume 1 sec. ( $FEV_1$ ) and mortality in chronic obstructive pulmonary disease (COPD) patients is studied by using the *Collaborative COHORTS to assess Multicomponents Indices of COPD in Spain* (COCOMICS) dataset (see [23]). In section 5 we present our conclusions. Finally, as appendix, we provide a set of **R functions** which are useful in order to handle, in practice, the proposed methodology.

## 2. Cumulative/dynamic ROC curve estimation

Conventionally, let  $\{y_i\}_{1 \leq i \leq N} = \{z_i, \delta_i, x_i\}_{1 \leq i \leq N}$  be an independent random sample (with size  $N$ ) where for  $1 \leq i \leq N$ ,  $z_i$  stands for the observed time;  $z_i = \min\{t_i, c_i\}$ , with  $t_i$  the time to event and  $c_i$  the censoring time,  $\delta_i$  is the status ( $\delta_i$  takes the value 1 if  $z_i = t_i$  and 0 if  $z_i = c_i$ ) and  $x_i$  stands for the (bio)marker value. From the Bayes theorem, the definition of sensitivity and specificity given in (1) and (2) are equivalent to

$$S_E^C(x, t) = \frac{\mathcal{P}\{X > x \wedge T \leq t\}}{\mathcal{P}\{T \leq t\}} = \frac{\int \mathcal{P}\{X > x \wedge T \leq t|y\}d\mathbf{F}_Y}{\int \mathcal{P}\{T \leq t|y\}d\mathbf{F}_Y}, \quad (5)$$

$$S_P^D(x, t) = \frac{\mathcal{P}\{X \leq x \wedge T > t\}}{\mathcal{P}\{T > t\}} = \frac{\int \mathcal{P}\{X \leq x \wedge T > t|y\}d\mathbf{F}_Y}{\int \mathcal{P}\{T > t|y\}d\mathbf{F}_Y}, \quad (6)$$

where  $y$  is the observed value ( $\{z, \delta, x\}$ ) and  $\mathbf{F}_Y$  its cumulative distribution function (CDF). Note that, in the sampling context, for  $i \in \{1, \dots, N\}$ ,  $\mathcal{P}\{X > x \wedge T \leq t | y_i\} = \mathcal{P}\{T \leq t | y_i\} \cdot I_{(x, \infty)}(x_i)$  ( $I_A(x)$  is the indicator function; takes the value 1 if  $x \in A$  and 0 otherwise). Then, if  $\hat{P}_i$  ( $= \hat{P}_i(N)$ ) is an adequate estimator for  $\mathcal{P}\{T > t | y_i\}$ , the empirical estimators for the sensitivity and the specificity can be written as,

$$\hat{S}_E^C(x, t) = \frac{\sum_{i=1}^N (1 - \hat{P}_i) \cdot I_{(x, \infty)}(x_i)}{\sum_{i=1}^N (1 - \hat{P}_i)}, \quad (7)$$

$$\hat{S}_P^D(x, t) = \frac{\sum_{i=1}^N \hat{P}_i \cdot I_{(-\infty, x]}(x_i)}{\sum_{i=1}^N \hat{P}_i}. \quad (8)$$

Obviously,  $z_i > t$  implies  $\hat{P}_i = 1$  and an event previous to  $t$  implies  $\hat{P}_i = 0$ ; therefore, for complete information, these estimators are the usual empirical ones. In addition, the consistency of the above estimators is direct if the estimator of  $\mathcal{P}\{T > t | y_i\}$  ( $1 \leq i \leq N$ ) has appealing conditions, particularly, that  $|\hat{P}_i - \mathcal{P}\{T > t | y_i\}| \rightarrow_N 0$  in probability. On the other hand, it is obvious that the resulting C/D ROC curve overcomes the drawbacks reported by the Kaplan-Meier based C/D ROC curve: for a fixed point  $t$ , it is monotone and always takes values below or equal to 1.

Different procedures can be used in order to estimate the above probability in those subjects which are not absolutely defined. We proposed a semi-parametric one; by using a proportional hazard Cox regression model; and a non-parametric proposal; by using directly the Kaplan-Meier estimator. From the proportional hazard Cox regression model we can estimate the hazard function  $\lambda(t) = \lambda_0(t) \exp\{\beta \cdot X\}$ , this quantity allows to compute  $\hat{P}_i = \hat{S}(t | X = x_i) / \hat{S}(z_i | X = x_i)$ , where  $\hat{S}$  is the survival function estimated from the Cox regression model. Unfortunately, due to  $X$  is usually a continuous variable, for the Kaplan-Meier method we can not directly estimate the probability for one particular value  $X = x_i$  and this condition is replaced by  $X \leq x_i$ ; then we select values satisfying  $X \leq x_i$  and compute the Kaplan-Meier estimator to obtain  $\hat{P}_i = \hat{S}_{KM}(t) / \hat{S}_{KM}(z_i)$ , where  $\hat{S}_{KM}$  is the survival function estimated by the Kaplan-Meier method referred to those subjects satisfying  $X \leq x_i$ .

Indeterminate or *mixed subjects* play a fundamental role. Note that an absolute uncertainty about the situation of the  $i$ th subject at time  $t$  ( $\hat{P}_i = 1/2$ ) implies that, when this subject is allocated into a group, we will commit an error with a probability of  $1/2$ , with independence of the group in which it will be allocated; in these cases, the capacity diagnostic of the studied biomarker will be limited.

In order to illustrate the problem, we have considered a real problem. Particularly, we have considered a dataset which contains information about 863 (=  $N$ ) kidney transplant patients. This data, free available within the R package `KMsurv`, has been previously used with the same goal by Wolf, Schmidt and Ulm [14]. Information about time to death and age of patients (in this case used as a mortality marker) were collected. Interested reader is referred to Klein and Moeschberger [24] for more details about the data. Figure 2 depicts the situation for the first five subjects when the considered time is 9 years: the patient with ID=3 died the seventh year, hence it is within the positive group; patients 4 and 5 were still alive at ninth year, therefore, they are within the negative group. However, the real situation for patients 1 and 2 are unknown. The probability that those patients are still alive nine years after the follow-up can be estimated by using the Kaplan-Meier estimator. Particularly, for the first subject, we must make the estimation considering only the subjects with age smaller than 46 resulting the estimation  $\hat{P}_1 = 0.88/0.95$  (= 0.86). Similarly, for the second subject, considering only the subjects with age smaller than 51, it is obtained the value  $\hat{P}_2 = 0.91$ ; in the proposed model, both are considered as *mixed subjects*.

Figure 3 depicts different ROC curve estimations. At left, in order to make the usual ROC curve ( $D_I$ ); the unclassified subjects, called *mixed*, were removed and a total of 140 positives and 17 negatives were finally considered. Both the Kaplan-Meier ( $K_M$ ) and the KNN ( $A_K$ ) based estimations for  $\mathcal{R}_t^{C/D}$  ( $t = 9$  yrs.) are also depicted (computed by using the R package: `survivalROC`). Observed differences between the  $A_K$  and the CIC estimations were negligible when the

span parameter (related with the KNN method) is close to zero. At right, the same usual ROC curve (plotted as references); and the C/D ROC curve estimations by using the method proposed above based on both the proportional hazard Cox regression ( $N_C$ ) and the non-parametric Kaplan-Meier estimator ( $N_K$ ).

### 3. Simulation study

In order to study the practical behaviour of the proposed methodology, a Monte Carlo simulation study was carried out. Similarly to Heatherty and Zheng [13], the joint distribution of  $\{\log(\text{Time}), \text{Marker}\}$  is a standard bivariate normal distribution with correlation coefficient  $\rho$  (cases -1/4 and -3/4 were studied). In addition, two different sample sizes ( $N = 100, 200$ ) were explored. The considered distribution for the censoring time,  $\log(C)$ , was also normal with standard deviation 1 and mean 0 ( $\mathcal{P}\{C < T\} = 1/2$ ) and 1.19 ( $\mathcal{P}\{C < T\} = 1/5$ ). The censoring time was drawn independently of the time

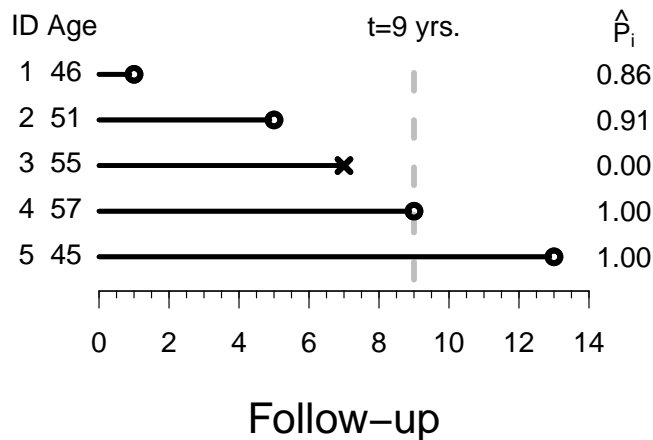

Figure 2: Schematic situation for IDs 1 to 5 of the kidney transplantation data.

to event, but not of (bio)marker values, which are related in such a way that  $\mathbb{E}[\log(C) \cdot M] = \tau$  (cases  $\tau = 0, 1/4$  were considered). C/D ROC curve estimations for  $\log(\text{Time}) = -1, 0, 1$  were computed based on the Kaplan-Meier estimator ( $K_M$ ), the KNN method with  $\text{span} = 0.01 \cdot N^{-1/5}$  ( $A_K$ ), the *direct method*, which removes the subjects with incomplete information, called *mixed subjects* in this paper ( $D_I$ ), and by using the proposed estimator based on both Cox regression ( $N_C$ ) and Kaplan-Meier estimator ( $N_K$ ). Figure 4 depicts the theoretical ROC curves from where the samples were drawn.

Table 1 shows the mean  $\pm$  standard deviation for  $0.01 \cdot \sqrt{N} \cdot \int_0^1 |\hat{\mathcal{R}}(p) - \mathcal{R}(p)| dp$ , where  $\mathcal{R}$  is the real C/D ROC curve and  $\hat{\mathcal{R}}$  is its estimation when  $\tau = 0$  (censoring time and (bio)marker values are drawn independently). Five studied methods performed similarly. Proposed  $N_C$  statistics obtained better results than  $N_K$  (note that in the simulated scenario it is satisfied the proportional hazard assumption) and it was the best of all in most cases. As expected, the observed differences between the proposed method and the other ones were

Figure 3: At left, direct ROC curve estimation ( $D_I$ ; removing the *mixed subjects*), Kaplan-Meier ( $K_M$ ) and KNN ( $A_K$ ; with  $\text{span} = 0.01 \cdot N^{-1/5}$ ) based cumulative/dynamic ROC curve estimations. At right,  $D_I$  (as references) and proposed estimations based on both Cox regression ( $N_C$ ) and Kaplan-Meier ( $N_K$ ).

clearer when the censored percentages were larger, particularly, for % C= 50 and  $\log(t) = 1$ , the proposed methodology achieved the best results.

Table 2 is the same as table 1 but considering that  $\tau = 1/4$ . Observed results were similar to the previous obtained ones. It seems that five considered estimators are robust respect to this correlation configuration between the (bio)marker and censoring time.

#### 4. Real-data application: the COCOMICS study

The proposed methodology is applied to study the capacity of forced ventilatory volume 1 sec. ( $FEV_1$ ) to predict mortality in chronic obstructive pulmonary disease (COPD) patients. With this goal, we consider the data of the *COllaborative COhorts to assess Multicomponent Indices of COPD in Spain* (COCOMICS study). This dataset included 11 Spanish cohorts with a total of 3,633 patients out of a total of 15,878.17 people per year. The interested reader is referred to Soriano et al. [25] and to Marin et al. [23] for complete information about the data. Figure 5 (up-left) depicts the Kaplan-Meier estimation with a 95% confidence interval for the COCOMICS data and the number of patients at risk at 1, 4, 7, 10 and 13 years.

Figure 4: Real ROC curves from where the samples were drawn.

Table 1: Mean  $\pm$  standard deviation of  $0.01 \cdot \sqrt{N} \cdot \int_0^1 |\hat{\mathcal{R}}(p) - \mathcal{R}(p)| dp$ , where  $\mathcal{R}$  is the real C/D ROC curve and  $\hat{\mathcal{R}}$  is its estimation, computed from 5,000 Monte Carlo iterations for  $\tau = 0$ .

In this dataset, differences between the five considered C/D ROC curve estimations at 10 years were really small (see Figure 5, top-right). The proposed estimator based on Kaplan-Meier showed itself more conservative than the other ones. At this point, 1,212 subjects were classified as positives and 198 were allocated into the negative group.

The prediction capacity of the (bio)marker (measured from the area under the ROC curve, AUC) was high along the follow-up time. It was about 0.73 at six months to decrease until 0.68 at two years (lowest value); after that, the diagnostic capacity increases until 0.76 at fourteen years. The integrated AUC along the follow-up time was 0.72. Figure 5 (down) depicts the AUC evolution with a 95% confidence interval (based on bootstrap replications).

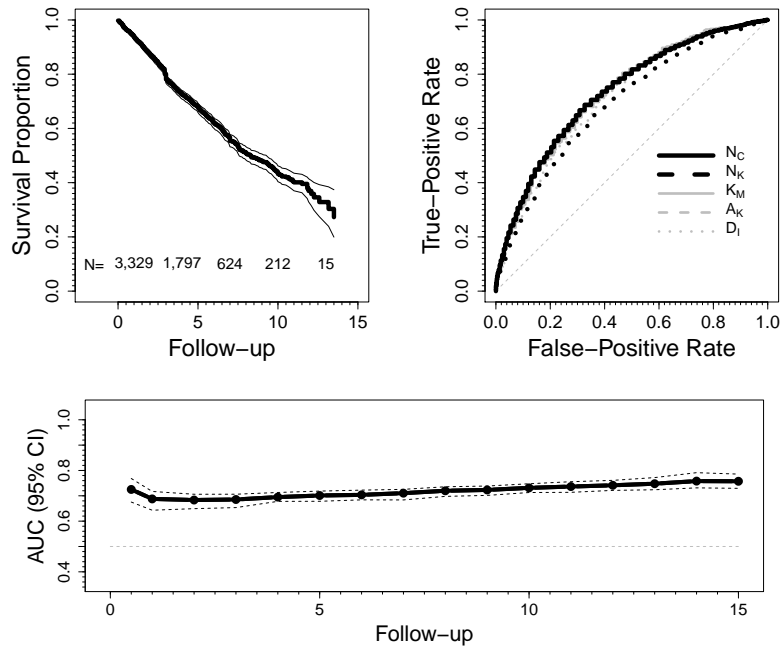

Figure 5: Kaplan-Meier survival curve estimation, top-left; C/D ROC curve estimation at ten years by using the five considered methods, top-right; AUC evolution with a 95% confidence interval, down.

## 5. Conclusions

In this paper the authors deal with the cumulative/dynamic ROC curve estimation in the presence of right-censored data. The proposed methodology assigns a probability of belonging to the negative group (respectively to the positive group) to those patients whose real status at considered point remains unknown (those censored before the considered point). This probability can be estimated from different methods; in this paper a semi-parametric (based on Cox regression) and a non-parametric (based on Kaplan-Meier) ones are considered. However, other methods can be used with this goal, even methods adapted to particular situations, ranging from competing-risk or multi-state contexts, to the non-monotone relationship ROC curve generalization [26]. The proposed estimator avoids the drawbacks of the previously existing ones; *i)* it is monotone and always ranges between 0 and 1, *ii)* it does not depend on smooth parameters. In the real-data example, the five considered estimators performed similarly, but simulation suggests that both  $N_C$  and  $N_K$  perform well and they are always better than the previous ones when the observed percentage of censorship is high. When some correlation between the (bio)marker and the censoring time is added, obtained results do not change substantially.

It should be noted that the direct method, removing the *undefined* subjects, usually obtains good results. However, do not use these individuals is not a good methodological practice; we are removing a particular subset of individuals which can have some interesting properties. For instance, if there exists some kind of relationship between the considered marker and the censoring time, the results will be strongly biased.

Perhaps, the main flaws in the presented methodology is the lack of a rigorous study of its theoretical properties. However, the proposed estimator has two different parts; the first one is the traditional ROC curve for complete data, and the second one is to assign, to each mixed subject, the probability that the event has not happened before the fixed point  $t$ . This probability depends

on several factors which are not previously clear. At this point, it is good to remark again the good results provided by the simulation study.

Finally, as appendix, we provide some R functions which compute the proposed methodology. The authors expect that a suitable R package will be soon available on the CRAN.

## Acknowledgements

The authors are grateful to the COCOMICS group for the permission to use the data.

## Appendix: R functions

The following R functions make the computes and display plots for the proposed C/D ROC curve estimator. The used notation is direct.

```
assignProbability <- function(stime, status, marker, predict.time, method=c('Cox', 'KM'),
                             undefinedIndices) {
  A function which assigns the probability of belonging to the negative group
  to those patients censored before the considered point
  - stime: observed time of each subject
  - status: status of each subject (takes the value 0 if the
            subject is censored and 1 otherwise)
  - marker: (bio)marker values
  - predict.time: considered time point
  - method: procedure used in order to estimate the probability;
            'Cox' stands for proposed method based on Cox regression
            'KM' stands for proposed method based on Kaplan-Meier estimator
  - undefinedIndices: indices of mixed subjects

  method <- match.arg(method)
  results <- 1:length(undefinedIndices)      vector results will contain the probabilities
                                             of mixed subjects

  Proposed method based on Cox regression

  if (method == 'Cox') {
    fit <- coxph(Surv(stime, status) ~ marker)
```

```

fits a Cox proportional hazard regression model whose
covariate is marker, i.e.,  $h(t) = h_0(t) \cdot e^{\beta X}$ 
md <- survfit(fit, newdata=data.frame(cbind(stime,status,marker)))
survival curves from the previously fitted Cox model

for (j in 1:length(undefinedIndices)) for each mixed subject
{
f <- approxfun(c(min(md$time)-1, md$time, max(md$time)+1),
c(1, md$surv[, undefinedIndices[j]], 0))
f contains a list of points which linearly interpolate given data points,
so it is an approximation of the survival function estimated from the
Cox regression model
results[j] <- f(predict.time) / f(stime[undefinedIndices[j]])
probability considered in mixed subjects based on
Cox regression model

if (is.na(results[j])) {
results[j] <- 1 if results[j] is a missing value, it takes the value 1, so the
j-th mixed subject is assigned to the negative group
}
}

```

Proposed method based on Kaplan-Meier estimator

```

} else if (method == 'KM') {
for (j in 1:length(undefinedIndices)) for each mixed subject
{
idx <- which(marker <= marker[undefinedIndices[j]])
idx contains the indices of those subjects whose marker is smaller than
or equal to the marker of the considered mixed subject
fit <- survfit(Surv(stime[idx], status[idx]) ~ 1)
survival curve from Kaplan-Meier estimator using only the
previous subjects
f <- stepfun(fit$time, c(1, fit$surv))
interpolating step function from survival curve above
results[j] <- f(predict.time) / f(stime[undefinedIndices[j]])
probability considered in mixed subjects based on
Kaplan-Meier estimator

if (is.na(results[j])) {
results[j] <- 1 if results[j] is a missing value, it takes the value 1, so the
j-th mixed subject is assigned to the negative group
}
}

```

```

    }
  }
  return(results)
}

```

return probabilities of mixed subjects

```

singleCdroc <- function(stime, status, marker, predict.time, method=c('Cox', 'KM')) {
  A function which returns the estimated sensitivity, specificity, AUC and other aspects
  of cumulative/dynamic ROC curve estimation based on the proposed methodology

  method <- match.arg(method)
  positiveIndices <- which(stime <= predict.time & status == 1)
    indices of those subjects whose event occurs before the considered
    time point (predict.time)

  negativeIndices <- which(stime > predict.time)
    indices of those subjects whose observed time is longer than predict.time

  undefinedIndices <- which(stime <= predict.time & status == 0)
    indices of those subjects censored before predict.time (mixed subjects)

  undefinedProb <- NULL

  if (length(undefinedIndices) > 0) {
    if there exists some mixed subjects
    undefinedProb <- assignProbability(stime, status, marker, predict.time, method,
    undefinedIndices)
    undefinedProb is a vector containing the probability of belonging to
    the negative group of mixed subjects
  }

  cutPoints <- c(min(marker) - 1, unique(sort(marker)), max(marker) + 1)
    different thresholds considered will be the different values of marker on the data;
    it will be also considered min(marker)-1 and max(marker)+1

  nSens <- length(positiveIndices) + sum(1 - undefinedProb)
    denominator of the estimator for the sensitivity considered in page 6, taking into
    account that "positive patients" have a probability of belonging to the negative
    group equals zero

  nSpec <- length(negativeIndices) + sum(undefinedProb)
    denominator of the estimator for the specificity considered in page 6, taking into
    account that "negative patients" have a probability of belonging to the negative
    group equals one

  sensitivity <- cutPoints

```

```

specificty <- cutPoints
for (i in 1:length(cutPoints))
{
sensitivity[i] <- (sum(marker[positiveIndices] > cutPoints[i]) +
sum(1 - undefinedProb[marker[undefinedIndices] > cutPoints[i]])) / nSens
specificity[i] <- (sum(marker[negativeIndices] <= cutPoints[i]) +
sum(undefinedProb[marker[undefinedIndices] <= cutPoints[i]])) / nSpec
}

auc <- integrate(rocFunction,0,1)
results <- list(TP=sensitivity, TN=specificity, undefinedProb=undefinedProb,
cutPoints=cutPoints, auc=auc$value, aucAbsError=auc$abs.error,
predict.time=predict.time, method=method)
attr(results, 'class') <- 'cdroc'
return(results)
}

```

both *sensitivity* and *specificity* vectors will have the same length than *cutPoints* vector

for each considered threshold for the (bio)marker

sensitivity estimation from expression in page 6

specificity estimation from expression in page 6

*rocFunction* contains a list of points which linearly interpolate given data points of the cumulative/dynamic ROC curve estimation

AUC estimation by adaptive quadrature of *rocFunction* over the unit interval

output:

- *TP*: sensitivity estimation, true positive rate
- *TN*: specificity estimation, true negative rate
- *undefinedProb*: probability of belonging to the negative group to those *mixed subjects*
- *cutPoints*: thresholds considered
- *auc*: AUC, the final estimate of the integral above
- *aucAbsError*: estimation of the modulus of the absolute error from integral estimation above
- *predict.time*: considered time point
- *method*: procedure used in order to estimate the probability considered; it can takes the value "Cox" or "KM"

return outputs above

```

cdroc <- function(stime, status, marker, predict.time, method=c('Cox', 'KM'), ci=FALSE,
                 boot.n=100, conf.level=0.95, seed=2032) {
  A function which returns outputs of singleCdroc function above, including some aspects
  about a conf.level confidence interval (if ci is TRUE) for the area under the
  cumulative/dynamic ROC curve
  - boot.n: number of bootstrap replications considered
  - seed: seed considered (for reproducibility)

  method <- match.arg(method)
