

An inverse Fast Multipole Method for imaging applications

Yuri Álvarez, *Member, IEEE*, José Ángel Martínez, *Member, IEEE*, Fernando Las-Heras, *Senior Member, IEEE*, Carey M. Rappaport, *Fellow, IEEE*

Abstract—An inverse Fast Multipole Method (FMM) for imaging applications is presented. The goal is the acceleration of an inverse source-based method for geometry reconstruction achieved by taking advantage of the multipole expansion properties of the scattered fields and reconstructed equivalent currents. By conjugating the FMM terms, it is possible to recover the equivalent currents from the scattered fields in just one step rather than using matrix inversion or cost function minimization. For the sake of simplicity, 2D problems where the objects-under-test having symmetry along one dimension are considered.

Index Terms— Imaging, Inverse Methods, Fast Multipole Method, Near Field characterization, Sources Reconstruction Method (SRM).

I. INTRODUCTION

INVERSE scattering methods are the basis for a wide range of applications in which non-destructive testing is required. Among these applications are medical diagnostics [1], detection of buried targets [2],[3] or security scanners for detecting concealed weapons [4].

The inverse scattering problem can be divided according to the targeted solution: either by profile or geometry retrieval (object-under-test external boundary) or by constitutive parameter retrieval.

In regard to the profile reconstruction, one of the possibilities is the parameterization of the object contour, thus imposing the proper boundary condition (e.g. zero tangential field in case of PEC) [5]-[7]. Further improvements could be

made with the introduction of auxiliary equivalent currents inside the object contour, which would improve the estimation of the scattered field [8]. In both cases, the resulting system of equations is non-linear, requiring non-linear optimization methods for solution.

Other methods are based on the so-called inverse source problem [9]-[12], where a set of equivalent currents are reconstructed in order to retrieve geometry and/or constitutive parameters. This inverse problem was initially reduced to a linear system of equations relating the scattered field and the equivalent currents [9]. The improvement of the inverse scattering method accuracy results in a non-linear formulation of the inverse scattering problem. For a general case, the non-linear problem must be solved using global search algorithms, as proposed in [10] using genetic algorithms, or with the Inexact-Newton method [11].

Even when the proposed problem is linear, one of the obstacles to be overcome is the computational cost, especially in those cases where the observation and reconstruction domains are electrically large, as in the case of burgeoning applications of millimeter wave radars. Moreover, some of the practical applications require quasi real-time processing. To reduce the computational time, two strategies can be adopted: i) Hardware improvement, as for example, the use of Graphics Processing Units (GPU), and ii) Introduction of acceleration methods in the inversion algorithms.

This work is focused on the second strategy and consequently presents an inverse Fast Multipole Method (FMM) [13]-[17], which is applied to accelerate an existing Volumetric Source Reconstruction Method [12]. While the FMM has been successfully applied in radar imaging [18] and in the Source Reconstruction Method (SRM) [19],[20], this work also presents a new forward solution of the inverse problem (i.e. one not requiring any matrix inversion).

II. THE INVERSE FAST MULTIPOLE METHOD

The Volumetric Source Reconstruction Method [12] is based on the volumetric equivalence principle that allows the substitution of the original sources (e.g. the induced currents on a metallic scatterer) with a volumetric equivalent current distribution that radiates the same field as the original sources.

For the sake of simplicity, the formulation will be given for a 2D case assuming a TM-polarized field as in [12]. The field radiated by an electric current distribution $\vec{J}_{eq}(\vec{\rho}) = J_{eq}(\vec{\rho})\hat{z}$ defined on a surface S' is given by (1):

$$\vec{E}_{scatt}(\vec{\rho}) = -\hat{z} \frac{jk_0\eta}{4} \int_{S'} \left\{ H_0^{(2)}(k_0 R(\vec{\rho}; \vec{\rho}')) J_{eq}(\vec{\rho}') \right\} dS' \quad (1)$$

Where $H_0^{(2)}$ is the Hankel function of 0-th order and second kind, $R(\vec{\rho}; \vec{\rho}')$ is the distance from the observation points $\vec{\rho} = \vec{\rho}(\rho, \phi)$ to the source points $\vec{\rho}' = \vec{\rho}'(\rho', \phi')$, k_0 is the wavenumber, and η is the intrinsic impedance. The integral equation above can be expressed as a linear system of equations where the impedance matrix ($Z_{E_{scatt}, J_{eq}}$) is approximated by the Fast Multipole Method (FMM) factors: disaggregation (D), translation (T), and aggregation (A) [13]:

$$\left(E_{scatt} \right) = \left(Z_{E_{scatt}, J_{eq}} \right) \left(J_{eq} \right) \approx (D)(T)(A) \left(\hat{J}_{eq} \right) \quad (2)$$

\hat{J}_{eq} is defined as $\hat{J}_{eq} = J_{eq} \cdot \Delta S$ where ΔS is the subdomain where the current is defined and J_{eq} is the current density in that subdomain. As indicated in [19],[20] one of the FMM advantages when it is applied to inverse problems is the fact that the observation and source domains are physically different, so in most cases, no adjacent groups are present. Even more, if the distance between the observation and source domains is large enough, the FMM far-field condition [15], [19] is satisfied for all the groups, allowing for the translation matrix simplification.

The aggregation (A) and disaggregation (D) factors are based on plane wave expansions with respect to the center of each group. In the case of the translation matrix (T), the far-field approach [15] is considered for a 2D formulation (3),

$$\begin{aligned} (A) &= e^{-jk_0 \hat{k} \cdot (\vec{C}_s - \vec{\rho}')} & (D) &= e^{-jk_0 \hat{k} \cdot (\vec{\rho} - \vec{C}_{obs})} \\ (T) &= e^{-jk_0 |\vec{C}_{obs} - \vec{C}_s|} \left(\left| \vec{C}_{obs} - \vec{C}_s \right| \right)^{-1/2} \end{aligned} \quad (3)$$

where $|\vec{C}_{obs} - \vec{C}_s|$ is the distance from the center of the source group \vec{C}_s to the center of the observation group \vec{C}_{obs} .

The FMM can also be applied to the inverse scattering problem. As the (A) and (D) terms are plane wave operators, it is possible to reverse the propagation direction by conjugating these terms, resulting in (D_i) and (A_i). The direction of the translator operator can be reversed by doing the same while the attenuation factor is inverted, (T_i) (Eq. (4)). Thus, the electric currents can be calculated from the scattered fields as indicated in Eq. (5):

$$\begin{aligned} (D_i) &= e^{+jk_0 \hat{k} \cdot (\vec{C}_s - \vec{\rho}')} & (A_i) &= e^{+jk_0 \hat{k} \cdot (\vec{\rho} - \vec{C}_{obs})} \\ (T_i) &= e^{+jk_0 |\vec{C}_{obs} - \vec{C}_s|} \left(\left| \vec{C}_{obs} - \vec{C}_s \right| \right)^{+1/2} \\ \left(\hat{J}_{eq} \right) &\approx (D_i)(T_i)(A_i) \left(E_{scatt} \right) \end{aligned} \quad (4)$$

Consequently, it is possible to recover the currents from the scattered fields in just one step without the use of matrix inversion or cost function minimization. The remarkable contribution of this approach is the computational cost savings. No linear system of equations needs to be solved with the currents calculated in a ‘‘forward’’ manner. In addition, because the FMM is an acceleration technique, it also contributes the reduction of the computational cost: while the

impedance matrix ($Z_{E_{scatt}, J_{eq}}$) size is equal to the number of observation points times the number of sources, the inverse FMM is implemented in such a way so that just the translation matrix (T_i), whose size is the number of observation groups times the number of source groups, is stored.

The inverse FMM is based on the far-field approach of the translation term (T_i). As stated in [15], the applicability of this approach is based on the following criterion (6):

$$\min \left\{ \left| \vec{C}_{obs} - \vec{C}_s \right| \right\} \gg \left(k_0 \max \{ D_g \} \right)^2 / 2 \quad (6)$$

where D_g is the size of the observation and sources groups. Note that for electrically large objects, the observation domain may be placed in the near field region of the object, but by making adjustments based on the group size, the FMM far-field condition can be still satisfied.

When considering multiple frequencies (N_{freq}) and incident plane waves (M_{inc}) illuminating the object-under-test [12], an inverse problem is solved independently for each incidence and frequency. The equivalent currents retrieved for each case are combined coherently [2] according to:

$$\vec{J}(\vec{\rho}') = \sum_{m=1}^{M_{inc}} \sum_{n=1}^{N_{freq}} \vec{J}^{m,n}(\vec{\rho}') e^{+jk_0^n (\vec{\rho}' \cdot \hat{k}_{inc}^m)} \quad (7)$$

where k_0^n is the wavenumber for the n -th frequency, and \hat{k}_{inc}^m is the unitary propagation vector for the m -th incident direction of the incident plane wave.

III. APPLICATION EXAMPLES

A. Metallic object profile reconstruction

In order to test the inverse FMM capabilities, an arbitrary object with a constant cross section on z-axis is chosen. The object is illuminated by 3 TM-polarized incident plane waves coming from $\phi = 0^\circ$, 120° and 240° , with frequencies from 700 to 1000 MHz in 20 MHz-step (35 % bandwidth with respect to the 850 MHz center frequency). The scattered field for each incidence and frequency is simulated using 2D-Method-of-Moments software, where the field is evaluated on a circle with radius $\rho = 10$ m, and sampled each $\Delta\phi = 2^\circ$. The field on the observation points will be affected by numerical noise to simulate virtual measurements.

The reconstruction domain is a 5 x 5.5 m rectangular domain discretized in 4x4 cm square patches ($0.13 \times 0.13 \lambda$ at the highest frequency, 1 GHz). This means that the resulting system of equations has 360 equations (number of field samples acquired in the circumferential observation domain) and 17388 unknowns (number of sources domain patches). As the number of incidences and frequencies is $M_{inc}=3$ and $N_{freq}=16$ respectively, 48 inverse problems have to be solved.

Regarding inverse FMM, no grouping is made on the observation domain (as only 360 points are considered), so the observation domain groups' size is zero. The sources domain is divided into 156 groups, each with a size of approximately $D_g = 0.6$ m. As the minimum distance from observation to source groups is 6.2 m, then:

$$\min \left\{ \left| \bar{C}_{obs} - \bar{C}_s \right| \right\} \approx 6.2 \text{ m} \quad \left(k_0 \max \{ D_g \}^2 \right) / 2 \approx 4 \text{ m} \quad (8)$$

So the FMM far-field criterion is (weakly) satisfied at the highest working frequency, 1 GHz. Fig. 1 represents the observation and source domains, and the inverse FMM grouping. With regard to the computational cost, Table 1 compares the calculation time of the Volumetric Source Reconstruction Method [12] and the Inverse FMM technique. Even with a 2D geometry, remarkable speed-up, about 40x, can be appreciated.

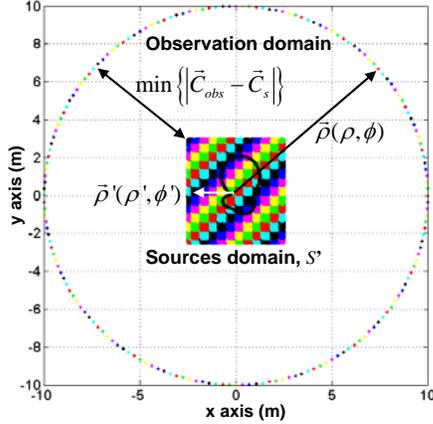

Fig. 1. Observation and sources domains, and FMM grouping.

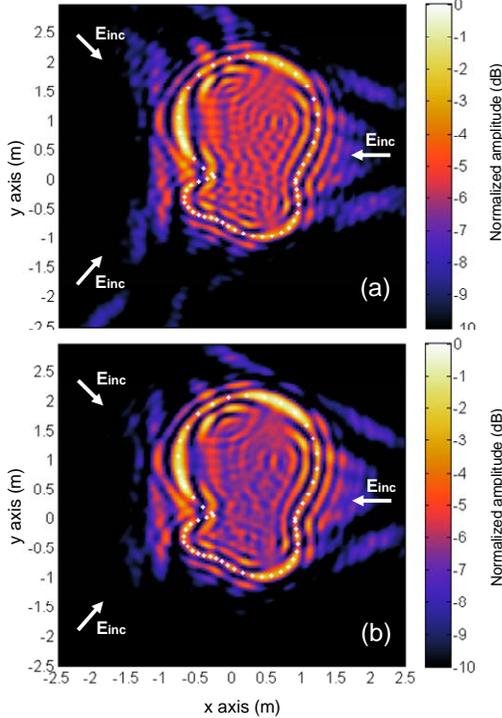

Fig. 2. Reconstructed equivalent currents (normalized amplitude, dB). (a) Using the Volumetric Source Reconstruction Method. (b) Using the Inverse FMM. 3 incidences and 16 frequencies are considered. The white dotted line represents the true profile.

Concerning the method accuracy, the retrieved equivalent electric currents using all the available information (16 frequencies and 3 incidences) are plotted in Fig. 2, generating a reasonable estimation of the object profile. It must be noted that the currents are combined coherently as indicated in (7).

In addition, when comparing the inverse FMM results Fig. 2 (a) to the ones given by the volumetric SRM Fig. 2 (b), no significant discrepancies are appreciated. The inverse FMM has also been tested for robustness against noise, plotting the reconstructed currents in Fig. 3: even for a 10 dB SNR, an acceptable profile estimation is achieved.

	Volumetric SRM	Inverse FMM
1 incidence, 1 freq.	62 s	1.5 s
1 inc., 16 freqs.	1074 s	21 s
3 inc., 16 freqs.	2874 s	62 s

Table 1. Calculation time.

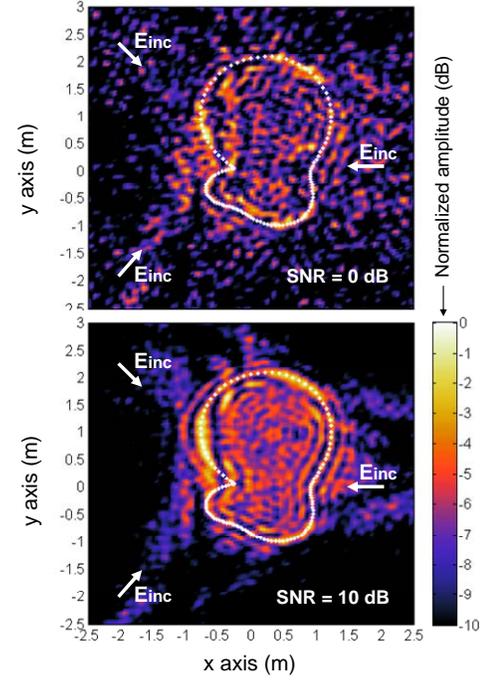

Fig. 3. Reconstructed equivalent currents (normalized amplitude, dB) using 3 incidences and 16 frequencies for different SNR values. The white dotted line represents the true profile.

B. Reconstruction of three metallic objects

In a second example, the method's capability for recovering the metallic profile of several objects is tested. The objects-under-test are the same as in [12], with an electric size of around 5λ at the highest working frequency. 16 frequencies from 700 to 1000 MHz are selected, resulting in a 35 % bandwidth with respect to the center 850 MHz frequency. The objects are illuminated by TM-polarized plane waves coming from 8 directions (0° to 315° , in 45° -steps). The scattered field is evaluated in a circumference of $\rho = 10 \text{ m}$, sampled each $\Delta\phi = 1^\circ$. It is assumed that the object-under-test profile is constant in the z direction, so again a 2D Method-of-Moments code has been used to evaluate the scattered fields. Noise is added with SNR of 40 dB.

The equivalent currents are reconstructed from the calculated scattered field in a square domain of $6 \times 6 \text{ m}$, discretized in $0.03 \times 0.03 \text{ m}$ square patches, corresponding to $0.1 \times 0.1 \lambda$ at 1 GHz (the highest frequency). This corresponds to an inverse problem with 360 equations (field samples) and 40401 unknowns (equivalent currents). If using all the

available information (8 incidences and 16 frequencies), 128 inverse problems must be solved.

The inverse FMM technique is used to calculate the currents. As the number of observation points is low, no grouping is done on this domain. In the case of the reconstruction domain, the problem is divided in groups of 0.4×0.4 m (i.e. $1.33 \times 1.33 \lambda$ at 1 GHz), resulting in 225 source groups, a value not too far from the square root of the number of source points. The 128 inverse problems are solved in ~ 5 min, implying 2.3 s per problem.

The combined currents (7) for different frequencies and incidences [2] are plotted in Fig. 4. The presence of three objects is a more challenging profile reconstruction problem, requiring the combination of 8 incidences for an accurate profile reconstruction (Fig. 4 (b)). Nevertheless, even with 4 incidences, the profile can be inferred.

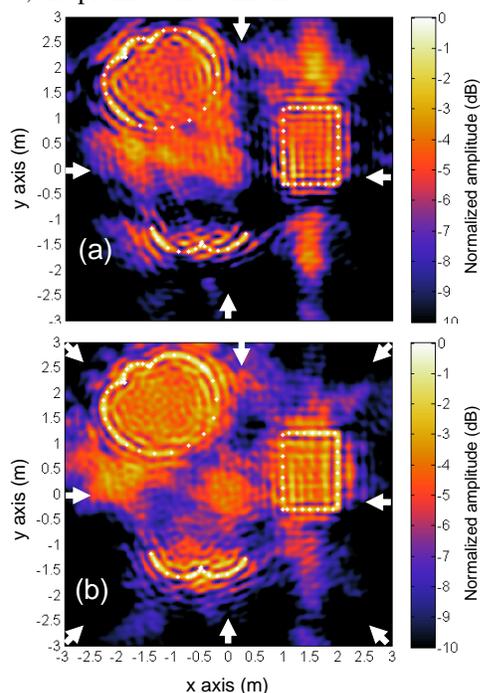

Fig. 4. Retrieved profile combining the equivalent currents for different incidences and frequencies. (a) 16 frequencies and 4 incidences. (b) 16 frequencies and 8 incidences. The white arrows indicate the arrival direction of the incident plane waves, and the white dotted line, the objects' profiles.

IV. CONCLUSION

An inverse FMM for reducing the computational cost of inverse electromagnetic scattering problems has been presented. The main contribution is the possibility of solving an inverse problem in a forward fashion, without compromising the profile reconstruction accuracy, but also reducing the calculation time by 40 times. The proposed technique is of a special interest in these imaging systems which require fast processing of the information in order to provide an immediate diagnostics of the object-under-test.
