Abstract. The effect of the heavy b-quark mass on the two, three and four-jet rates is studied using LEP data collected by the DELPHI experiment at the Z peak in 1994 and 1995. The rates of b-quark jets and light quark jets ($\ell = uds$) in events with $n = 2, 3$, and 4 jets, together with the ratio of two and four-jet rates of b-quarks with respect to light-quarks, $R_n^{b\ell}$, have been measured with a double-tag technique using the CAMBRIDGE jet-clustering algorithm. A comparison between experimental results and theory (matrix element or Monte Carlo event generators such as PYTHIA, HERWIG and ARIADNE) is done after the hadronisation phase.

Using the four-jet observable $R_4^{b\ell}$, a measurement of the b-quark mass using massive leading-order calculations gives:

$$m_b(M_Z) = 3.76 \pm 0.32 \,(\text{stat}) \pm 0.17 \,(\text{syst}) \pm 0.22 \,(\text{had}) \pm 0.90 \,(\text{theo}) \,\text{GeV}/c^2 \,.$$

This result is compatible with previous three-jet determinations at the M_Z energy scale and with low energy mass measurements evolved to the M_Z scale using QCD renormalisation group equations.

1 Introduction

Mass corrections to the $Z \to b\bar{b}$ coupling are of order (m_b^2/M_Z^2), which is too small to be measured at LEP and SLC. For some inclusive observables, like jet-rates, the effect is enhanced as $(m_b^2/M_Z^2)/y_{\text{cut}}$, where y_{cut} is the jet resolution parameter [1]. The effect of the b-quark mass in the production of three-jet event topologies at the Z peak has for instance already been measured at LEP and SLC [2–6]. Multi-jet topologies with b-quarks appear both as signal and background in searches and precision measurements at current and future colliders. Their study, together with that of the gluon emission from massive quarks, is an effective tool to probe the fundamental short-distance QCD features of the Standard Model and is important to test the modelling of b and light-quark jets available in calculations and generators.

This study generalizes the methods described in [2, 3, 7] and presents the measurement of the normalized n-jet production partial widths for Z-decays into b-quark or light quark pairs:

$$R_{n=2,3,4}^q(y_{\text{cut}}) = \left[\frac{\Gamma_n(y_{\text{cut}})}{\Gamma_{\text{tot}}} \right]^{Z \to q\bar{q}} \quad q = b, \ell \,(\ell = uds) \,, \tag{1}$$

depending on the y_{cut} value of the CAMBRIDGE jet-clustering algorithm [8] which is used here.

The effect of the heavy b-quark mass on jet rates is studied by measuring the double-ratio observable:

$$R_{n=2,3,4}^{b\ell} = R_n^b / R_n^\ell \,. \tag{2}$$

The DELPHI data collected during the years 1994 and 1995 at a centre-of-mass energy of $\sqrt{s} \approx M_Z$ have been analysed. Experimental results are compared to the hadronic final state simulated by the fragmentation models of PYTHIA 6.156 [9, 10], HERWIG 6.2 [11, 12] and ARIADNE 4.08 [13] and to matrix element (ME) calculations folded with a hadronisation correction. Therefore, the data are corrected for detector and kinematical effects, while ME calculations, computed at parton level, are corrected for hadronisation.

---

[b] e-mail: jan.timmermans@cern.ch

In order to extract the b-quark mass information from $R_n^{b\ell}$ measurements, massive ME calculations performed in terms of both the pole mass M_b and the running mass $m_b(\mu)$ are used. Jet-rate calculations are only available to $\mathcal{O}(\alpha_s^2)$ [14–16], therefore massive four-jet observables can only be described to leading-order (LO) accuracy. The b-quark mass obtained from $R_4^{b\ell}$ using such LO calculations is compared to the three-jet results [7] and to mass values at threshold [17] evolved to the M_Z scale using renormalisation group equations (RGE). An approximate massless NLO correction is also tried as an improvement.

The precision of b-mass measurements from three-jet events is limited by systematic uncertainties (hadronisation, b-tagging and theory). The four-jet observable $R_4^{b\ell}$ has a larger statistical error but its sensitivity to the b-quark mass is higher because, most probably, the emission of two gluons is involved. The four-jet topology thus provides a complementary measurement in which the systematic uncertainties can be expected to be partly different. In this analysis, flavour jet-rates are measured using a double-tag technique which measures signal and background efficiencies from data in a self-calibrating way, reducing the systematics and allowing for a useful cross-check of previous measurements [7].

2 The DELPHI detector

DELPHI was a hermetic detector located at the LEP accelerator, with a superconducting solenoid providing a uniform magnetic field of $1.23\,\text{T}$ parallel to the beam axis throughout the central tracking device volume. A detailed description of its design and performance is presented in [22, 23].

In the DELPHI coordinate system, the z-axis is oriented along the direction of the electron beam. The polar angle θ is measured with respect to the z-axis, ϕ is the azimuthal angle in the plane transverse to the z-axis and $R = \sqrt{x^2 + y^2}$ is the radial coordinate.

The main tracking devices in DELPHI were the silicon Vertex Detector (VD), a jet chamber Inner Detector (ID) and a time projection chamber (TPC). They were located in the immediate vicinity of the interaction region to reduce the amount of material between the beam and the detector. At a larger distance, the tracking was completed

by a drift chamber Outer Detector (OD) covering the barrel region ($40° ≤ θ ≤ 140°$) and two sets of drift chambers, FCA and FCB, located in the endcaps.

The VD was the detector closest to the interaction point. In 1994 and 1995 it consisted of three coaxial cylinders, the inner and outermost ones consisting of double-sided detectors with orthogonal strips, allowing the measurement of both $R\phi$ and z coordinates.

Electron and photon identification was provided by electromagnetic calorimeters: the High Density Projection Chamber (HPC) in the barrel and a lead-glass calorimeter (FEMC) in the endcaps. Hadronic energy was measured in the hadronic calorimeter (HCAL).

3 Data analysis

First, the sample of Z hadronic decays, i.e. $Z→q\bar{q}$ events was selected. Then the different jet-topologies were identified using the CAMBRIDGE jet-clustering algorithm [8][1], and b and light-quark samples were separated using the DELPHI flavour tagging methods, based on properties of the long-lived heavy B-hadrons. Experimental results were then corrected for detector and acceptance effects in two different ways, depending on the observable and topology, as explained in Sect. 3.3. Matrix element and event generator predictions were corrected for hadronisation effects from the parton to the hadron level. The parton level is defined as the final state of the parton shower (in PYTHIA and HERWIG) or dipole cascade (in ARIADNE) in the simulation, before hadronisation. These corrections are discussed in Sect. 4.

3.1 Event selection

Total numbers of $1\,484\,000$ and $750\,000$ hadronic Z boson decays, collected at the Z resonance by DELPHI during the years 1994 and 1995, respectively, have been analysed in order to study mass effects in multi-jet topologies.[2]

Hadronic events were selected in the same way as in [2,3] (see Table 1, upper):

– Charged and neutral particles were reconstructed as tracks and energy depositions in the detector. A first selection was applied to ensure a reliable determination of their momenta and energies.
– The information from the accepted tracks was combined event-by-event and hadronic events were selected according to global event properties.

Finally, a total sample of $1\,150\,000$ Z hadronic decays was selected. Then jets were reconstructed with the CAMBRIDGE algorithm. In order to reduce the impact of particle losses and wrong energy-momentum assignment

---

[1] In our analysis, the values of the ordering and resolution parameters were taken to be equal, $v_{ij} = y_{ij}$.

[2] Earlier data samples were not considered as the VD setup was less complete and resulted in a less precise flavour identification, which is crucial for this analysis.

Table 1. (*Upper*) Particle and event selections: p_{ch} is the momentum of charged particles, L their measured track length, d their impact parameter with respect to the interaction point and q_i their charge, E_{cl} is the energy of neutral clusters in the calorimeters, N_{ch} is the number of charged particles and E_{ch} their total energy in the event. (*Lower*) Kinematical selections for jets in accepted events: $θ_{thrust}$ is the polar angle of the thrust of the event, N_j^{ch} the charged multiplicity in the jet, E_j the jet energy and $θ_j$ the angle between the jet and the beam axis. For three-jet events, an additional planarity cut is applied on the sum of all jet pair angles, ϕ_{ij}

Charged	$p_{ch} ≥ 0.1 \text{ GeV}/c$
Particle	$25° ≤ θ ≤ 155°$
Selection	$L ≥ 50 \text{ cm}$
	$d ≤ 5 \text{ cm in } R\phi \text{ plane}$
	$d ≤ 10 \text{ cm in } z \text{ direction}$
Neutral	$E_{cl}^{HPC} ≥ 0.5 \text{ GeV}, 40° ≤ θ ≤ 140°$
Cluster	$E_{cl}^{FEMC} ≥ 0.5 \text{ GeV}, 8° ≤ θ ≤ 36°$
Selection	$E_{cl}^{FEMC} ≥ 0.5 \text{ GeV}, 144° ≤ θ ≤ 172°$
	$E_{cl}^{HAC} ≥ 1 \text{ GeV}, 10° ≤ θ ≤ 170°$
Event	$N_{ch} ≥ 5$
Selection	$E_{ch} ≥ 15 \text{ GeV}$
	$|\sum_i q_i| ≤ 6, i = 1, \dots, N_{ch}$
	No particle with $p_{ch} ≥ 40 \text{ GeV}/c$

2-jet	$45° ≤ θ_{thrust} ≤ 135°$
3-jet	$45° ≤ θ_{thrust} ≤ 135°$
	$N_j^{ch} ≥ 1$
	$E_j ≥ 1 \text{ GeV}$
	$25° ≤ θ_j ≤ 155°$
	$\sum_{ij} \phi_{ij} ≥ 359°, i < j$
4-jet	$32° ≤ θ_{thrust} ≤ 148°$
	$N_j^{ch} ≥ 1$
	$E_j ≥ 1 \text{ GeV},$
	$25° ≤ θ_j ≤ 155°$

to jets, further kinematical selections were applied, which were slightly different for each jet topology (see Table 1, lower).

Simulated events were produced with the DELPHI simulation program DELSIM [23], based on PYTHIA 7.3 tuned to DELPHI data [24,25], and were then passed through the same reconstruction and analysis chain as the experimental data. The simulated events were reweighted in order to reproduce the measured rates of $b\bar{b}$ and $c\bar{c}$-quark pairs arising from the gluon splitting processes [26] ($g_{b\bar{b}} = 0.00254 ± 0.00051$, $g_{c\bar{c}} = 0.0296 ± 0.0038$), which are significantly larger than those in the standard simulation.

3.2 b-tagging

The identification of b-quark events in DELPHI was based on the properties of a B-hadron such as its large mass and the large impact parameter of its decay products. A jet estimator variable X_{jet} was built as an optimal combination of five discriminating variables [27]. The most discriminant one was the probability of having all charged particles

in the jet produced at the event interaction point. The use of this variable alone defined the impact-parameter technique. The additional variables were used only when a secondary vertex (SV) was reconstructed. These variables were, for all particles attached to the SV: the invariant mass, the fraction of the charged jet energy, the sum of all transverse momenta and the rapidity of each particle. The information from all five variables was combined into a single estimator $X_{\rm jet}$ in an almost optimal way which provided discrimination between heavy and light jets with high purity and efficiency. To obtain b(light)-quark enriched samples, jets with an estimator value above (below) a given threshold $X_{\rm jet} \geq X_{\rm jet}^b$ ($X_{\rm jet} < X_{\rm jet}^\ell$) were selected. To tag events, the value of the two highest b-tagging jet variables were combined into an event estimator, $X_{\rm ev} = X_{\rm jet}^1 + X_{\rm jet}^2$.

In the present analysis, this approach has been associated to a double-tag technique [28], which measures flavour-tagging efficiencies directly from data.

Using the two jets with highest b-tagging variables as the *flavour jets* (jets which are expected to contain a primary quark) makes no distinction between primary quarks originating in the Z decay and secondary production of b- and c-quarks from gluons ($g \to b\bar{b}, c\bar{c}$), a process referred to as gluon splitting and which constitutes a significant part of the systematic uncertainty in multi-jet flavour-observables (see Sect. 4.3).

To reduce the sample contamination from gluon splitting in four-jet events, the flavour jets were defined as follows: the most energetic jet in each event is identified as the first flavour jet. Remaining jets are ordered by angular proximity to it. The closest jet is discarded making the hypothesis that it is a gluon coming from the same primary quark. The second b(light)-flavour jet is that with the highest b-tag (lowest b-tag) estimator among the two remaining jets. In this way, energy and angle information is combined to define the flavour-jets. As an additional selection, an event is not classified as $b\bar{b}$ if the most b-tagged jet is not among the two most energetic jets; this last selection reduces the uncertainty from $g_{b\bar{b}}$ and $g_{c\bar{c}}$ by a factor two. The effect of the remaining contamination due to gluon splitting is included in the gluon-splitting uncertainty and is well below the statistical uncertainties (Tables 4 and 5).

3.3 Overview of the correction method

3.3.1 Event-tag

To correct the two-jet observable $R_2^{b\ell}$ for detector effects and the flavour tagging procedure, the event-tag method described in reference [2, 3] was used:

$$
R_2^{b\ell} = \frac{\left[c_B^\ell d_{2B}^\ell + R_2^{c\ell} c_B^c d_{2B}^c \right] - \left[c_L^\ell d_{2L}^\ell + R_2^{c\ell} c_L^c d_{2L}^c \right] R_2^{b\ell - det}}{c_L^b d_{2L}^b R_2^{b\ell - det} - c_B^b d_{2B}^b},
$$

(3)

where the measured rate $R_2^{b\ell - det}$ is corrected by using purities of the inclusive samples, $c_Q^q = N_Q^q / N_Q$ (the fraction of

Table 2. Flavour composition of the 1994 sample ($y_{\rm cut} = 0.0065$). The number of events in the inclusive and 2-jet samples are shown separately for B and $L = uds$ tagged events for the chosen flavour-tagging working points. Purity and efficiency are also shown. Similar numbers were found with the 1995 data

| Flavour | Inclusive | Event-tag method | | Purity | Efficiency |
		2 jets	cut		
B	111 440	75 147	$X_{\rm ev} \geq 1.10$	98%	38%
L	678 282	414 912	$X_{\rm ev} < 0.40$	73%	58%

$q\bar{q}$ events tagged in the Q category), and detector corrections taken from the DELSIM simulation, $d_{2Q}^q = R_{2Q}^q / R_2^q$ (where R_{2Q}^q is the two-jet rate of $q\bar{q}$ events tagged as Q). The factor $R_2^{c\ell} = R_2^c / R_2^\ell$ is taken from the simulation. Table 2 summarizes the number of events selected in the 1994 data in each flavour sample for the chosen working points of purity $P_B = c_B^b = 98\%$ ($P_L = c_L^\ell = 73\%$, $L = uds$) and efficiency of $\epsilon_B^b = 38\%$ ($\epsilon_L^\ell = 58\%$) for b-flavoured (light-flavoured) events (where $\epsilon_Q^q = N_Q^q / N_q$, the ratio of tagged events of a given flavour to the total number of events of the same flavour), respectively.

The event-tag method has the advantage of applying the flavour-tagging procedure only in the inclusive sample, before events are classified into jet topologies.

3.3.2 Double-jet tag

The event-tag method, if the jet sample is topologically very different from the inclusive one, can introduce important biases. To prevent this, in the $R_4^{b\ell}$ measurement b-tagging is applied to jets. The observable in (2) is rewritten as:

$$
R_4^{b\ell} = \left(\frac{\Gamma(Z \to \ell\bar{\ell})}{\Gamma(Z \to b\bar{b})} \right) \frac{N_4^b / N_4}{N_4^\ell / N_4} = \left(\frac{1 - R_b - R_c}{R_b} \right) \frac{N_4^b}{N_4^\ell}.
$$

(4)

The global normalisation can be obtained directly from the world average values of R_b and R_c [17]:

$$
R_b = 0.21629 \pm 0.00066 ,
$$
$$
R_c = 0.1721 \pm 0.0030 ,
$$

(5)

which implies a $\pm 6\text{‰}$ uncertainty on $R_4^{b\ell}$. A double-tag technique is used: the total number of four-jet events, N_4, the corresponding numbers for a given flavour N_4^q, $q = b, udsc$, and the tagging efficiencies ϵ_B^b and ϵ_{UDSC}^{udsc} are obtained from comparing the number of four-jet events where two jets are tagged as b or $udsc$ to the number of events where a single jet is tagged. This is done by solving the following set of equations:

$$
\mathcal{N}_4 = \left\{ N_4^b \epsilon_h^b + \left(N_4 - N_4^b \right) \epsilon_h^{\rm non-b} \right\} ,
$$

(6)

$$
\frac{1}{2} \mathcal{N}_{4B} = \left\{ N_4^b \epsilon_h^b \epsilon_B^b + \left(N_4 - N_4^b \right) \epsilon_h^{\rm non-b} \epsilon_B^{\rm non-b} \right\} ,
$$

(7)

$$
\mathcal{N}_{4BB} = \left\{ N_4^b \epsilon_h^b \epsilon_{BB}^b + \left(N_4 - N_4^b \right) \epsilon_h^{\rm non-b} \epsilon_{BB}^{\rm non-b} \right\} ,
$$

(8)

Table 3. Flavour composition of the 1994 sample ($y_{\text{cut}} = 0.0065$) tagged as n-jet b-quark (B) and $udsc$-quark events (L) for the different jet topologies analysed, $n = 2, 3$ and 4 jets. Four-jet tagging uses the method described in Sect. 3.2 for the definition of flavour jets. Similar numbers were found with the 1995 data

Topology	Q	Double-tag method		Purity	Efficiency
		QQ	cut		
2 jets (B)	136 228	35 187	$X_{2j} \geq +0.33$	92%	57%
2 jets (L)	640 757	243 716	$X_{2j} < -0.92$	95%	78%
3 jets (B)	66 034	15 356	$X_{3j} \geq +0.19$	87%	53%
3 jets (L)	362 396	147 605	$X_{3j} < -0.64$	93%	84%
4 jets (B)	10 720	2191	$X_{4j} \geq +0.05$	84%	35%
4 jets (L)	91 042	36 773	$X_{4j} < -0.64$	89%	86%

and equivalent equations for the $udsc$-tagged samples. The left hand side of these equations are the measured quantities. $\mathcal{N}_4$ is the number of measured four-jet events. For each event the two jets which are most likely to contain a primary quark (flavour jets, see above) are selected and the flavour identification is done independently for both jets: $\mathcal{N}_{4B}$ is the number of jets tagged as B (with a maximum possible value of $2\mathcal{N}_4$, two from each event) and $\mathcal{N}_{4BB}$ is the number of events where the two flavour jets are simultaneously tagged as B. With this method, the jet-rates R_4^b and R_4^ℓ are measured independently, together with the efficiencies ϵ_B^b and ϵ_{UDSC}^{udsc}. To accomplish this, double-jet tagging efficiencies ϵ_{QQ}^q are related to the single jet-tagging efficiencies through correlation factors defined from

$$\epsilon_{QQ}^q = N_{QQ}^q / N^q \equiv \epsilon_Q^q \epsilon_Q^q \left(1 + \rho_Q^q\right).$$

Here, charm-events have been included in the $udsc$-tagged category: the light-quark content N_4^ℓ is extracted from N_4^{udsc} after dividing by a factor $(1 + N_4^c/N_4^\ell)$ obtained from Monte Carlo event generators. Only hadronic event-selection efficiencies for each flavour, $\epsilon_h^q = N_q^{\text{sel}}/N_q$, mistagging efficiencies, $\epsilon_Q^{\text{non}-q}$ and $\epsilon_{QQ}^{\text{non}-q}$, and flavour correlations for b and light-tagging are computed from the simulation.

This procedure can be easily generalised to cover $n = 2, 3$-jet topologies in order to measure both jet-rates (R_n^b, R_n^ℓ) and the double-ratios $(R_{2,3}^{b\ell})$ independently. Due to the 6‰ uncertainty from the global normalisation, the double-tag measurements for $R_{2,3}^{b\ell}$ are less precise than the corresponding event-tag result. However, they serve as a useful cross-check both of the final result and on the consistency between data and simulation for the flavour-tagging efficiencies.

Results with this method have a better stability with respect to the value of the flavour-tagging threshold, and are more consistent with each other.[3] The flavour composition of the 1994 sample is shown as an example in Tables 2

---

[3] From the relation $N_4 = N_4^b + N_4^{udsc}$, the double-ratio $R_4^{b\ell}$ can be obtained independently in two ways, starting either from R_4^b or R_4^ℓ.

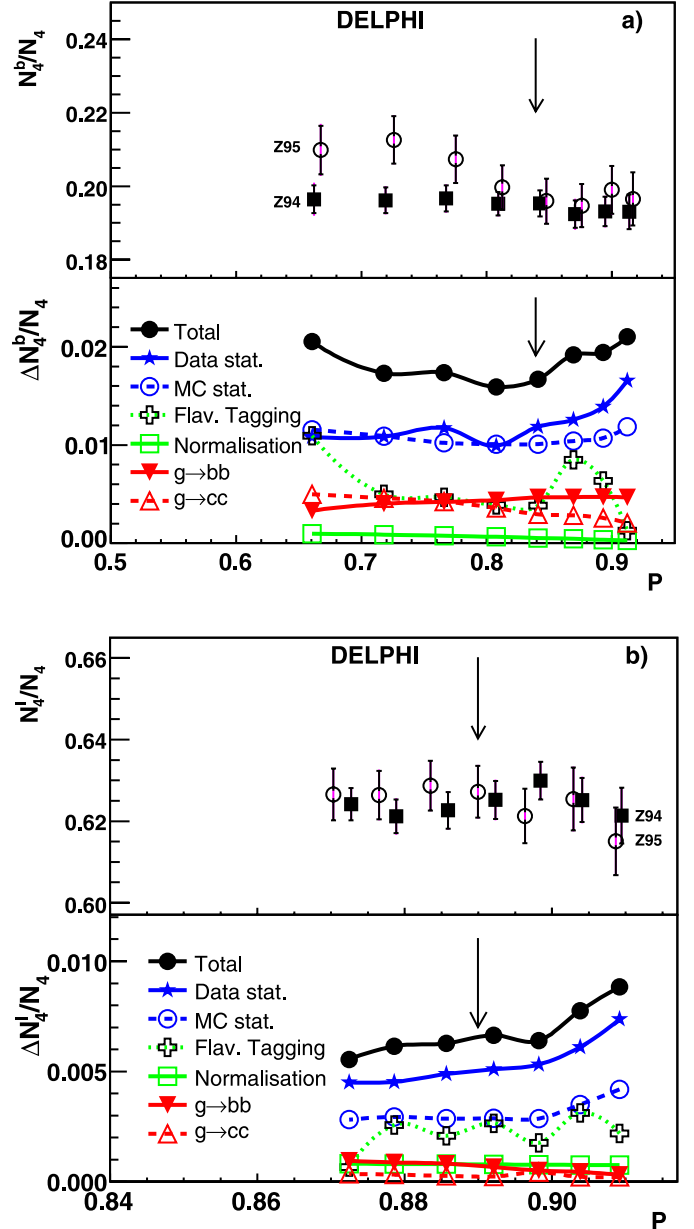

Fig. 1. Four-jet rate and its uncertainty as a function of **a** the b-purity and **b** the light-purity ($\ell = udsc$, $y_{\text{cut}} = 0.0065$). Chosen working points are marked with *arrows*, and correspond to efficiencies of $\epsilon_B^b = 35\%$ and $\epsilon_L^\ell = 86\%$, respectively. The statistical (data and simulation) and total uncertainties are shown

and 3. The stability obtained in the case of the four-jet rates is shown in Fig. 1 for the 1994 and 1995 data samples.

4 Results

The single-flavour jet rates R_n^q, $n = 2, 3, 4$-jets, and the four-jet observable $R_4^{b\ell}$, are measured with the double-tag technique, while the two-jet observable $R_2^{b\ell}$ is measured using the event-tag method described in [2, 3]. A de-
Fig. 2. Comparison between the measured b and $\ell = uds$ jet-rates and predictions from the PYTHIA 6.156, HERWIG 6.2 and ARIADNE 4.08 generators. **b–d** Ratio of data to the different generators. The *shaded area* shows the one standard deviation relative uncertainty (statistical and systematic added in quadrature) of the experimental measurement

scription of the experimental uncertainties considered in the analysis is given in Sect. 4.3. Theoretical uncertainties, arising in the comparison between ME predictions and the four-jet observable, are discussed in Sects. 4.5 and 4.6.

4.1 Single jet-rates, R_n^q

The measured R_n^q rates ($n = 2, 3, 4$ jets, $q = b$ or $\ell = uds$) are shown in Fig. 2a together with predictions from the PYTHIA 6.156, HERWIG 6.2 and ARIADNE 4.08 generators tuned to DELPHI data [24, 25] (see Sect. 4.6 for the choice of the b-quark mass parameter in the generators). The detailed breakdown of the uncertainties of the measured jet-rates is shown in Table 4. The R_3^ℓ measurements

in 1994 and 1995 were found to be incompatible with each other at the two standard deviations level, indicating that some systematic effect was not taken into account in the three-jet light-quark rate. The systematic tagging uncertainty in R_3^ℓ was increased in order to fully cover this difference. Only the uncertainty in R_3^ℓ was increased since the b-tagging was developed from 2-jet events yielding reliable R_2^ℓ results, and in 4-jet events the b-tagging applies different cuts on angle and energy. The consistency of the experimental results and the prediction from the three event generators is shown in Fig. 2b–d. The HERWIG 6.2 and ARIADNE 4.08 generators provide a reasonable description of the six observables in the region of y_{cut} between 0.001 and 0.010. PYTHIA 6.156 gives the best description of R_2^b, but is inconsistent with the other jet-measurements at the three standard deviations level.

Table 4. Breakdown of uncertainties for the R_n^q jet-rate measurements at a reference $y_{\text{cut}} = 0.0065$. The definition of each systematic contribution is given in Sect. 4.3

4.2 Double-ratios, $R_n^{b\ell}$

The measured double-ratios $R_n^{b\ell}$ ($n = 2, 3, 4$ jets) are shown in Figs. 3 and 4 together with predictions from the PYTHIA 6.156, HERWIG 6.2 and ARIADNE 4.08 generators tuned to DELPHI data [24, 25] (see Sect. 4.6 for the choice of the b-quark mass parameter in the generators).

Results for $R_2^{b\ell}$ and $R_3^{b\ell}$ from the event-tag and double-tag methods are shown in Fig. 3 (event-tag results for $R_3^{b\ell}$ are taken from [7]). $R_2^{b\ell}$ is not described well by either of the generators in the full y_{cut} range. In all cases, both methods give consistent results within one standard deviation. A better experimental precision is found with the event-tag, because the global normalisation uncertainty is absent in this case and because flavour-tagging uncertainties cancel to first order in the products $c_Q^q d_{nQ}^q$ (see (3)). Statistical uncertainties in the event-tag result are also smaller, as more data events are considered and as statistical fluctuations are partially reduced in the ratios of the jet and inclusive samples. The detailed breakdown of the uncertainties of the measured double-ratios is shown in Table 5 for the event-tag method.

The $R_4^{b\ell}$ result with the double-tag method is shown in Fig. 4a, while the experimental systematics breakdown is summarized in Table 5. At y_{cut} values above 0.004 the measurement is dominated by statistical uncertainties, while for very low values of y_{cut} the data samples increase and the global normalisation uncertainty dominates. Gluon splitting uncertainties are kept low in the whole y_{cut} range thanks to the dedicated anti-gluon splitting cut (see Sect. 3.2). HERWIG provides the best description, being compatible with the experimental data in the whole y_{cut} range. However, the PYTHIA prediction is only 1.5 standard deviations away in the large y_{cut} region; ARIADNE provides a good description of the data in the region $y_{\text{cut}} \geq 0.005$, while for lower values of y_{cut} it tends to underestimate the mass effect.

Table 5. Breakdown of uncertainties for the $R_n^{b\ell}$ ($n = 2, 3, 4$) double-ratio measurements. The three-jet result is taken from [7] and shown here for completeness. The two and three-jet measurements are based on the event-tag method, while $R_4^{b\ell}$ uses the double-tag technique as explained in Sect. 3.3. The b-mass values (running and pole) extracted from $R_4^{b\ell}$ at reference $y_{\text{cut}} = 0.0065$ are also shown, both for the massive LO ($M_b = m_b(M_Z)$) and approximate NLO calculations. Experimental and modelling uncertainties (experimental tuning and hadronisation model in the simulation) are detailed separately

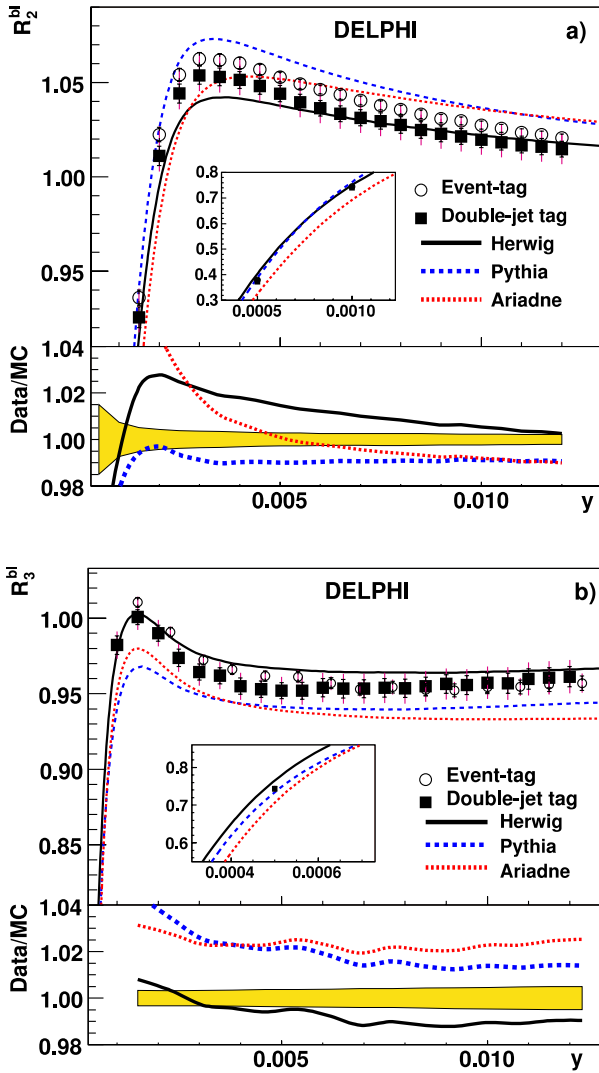

Fig. 3. Comparison between the event-tag (*empty circles*) and double-tag (*full squares*) techniques for the measured **a** $R_2^{b\ell}$ and **b** $R_3^{b\ell}$ observables. The event-tag result of $R_3^{b\ell}$ is taken from [7]. The combined statistical (*inner bars*) and total uncertainty of the experimental data are shown. The results are compared to the predictions from the HERWIG 6.2 (*solid*), PYTHIA 6.156 (*dashed*), and ARIADNE 4.08 (*dotted*) event generators. The *lower insets* of the plots show the ratio of data to the different generators. Also shown as the *shaded area* is the one standard deviation relative uncertainty (statistical and systematic added in quadrature) of the data

4.3 Experimental uncertainties

Experimental uncertainties arise in the process of correcting the detector-level measurement to hadron level, and are due to imperfections in the physics and detector modelling in the DELSIM simulation used in the correction procedure. The following sources have been considered in this analysis:

– *Statistical*: These uncertainties are due to the limited size of the experimental and simulated data samples. They are estimated from a toy simulation
Fig. 4. **a** Comparison between the $R_4^{b\ell}$ measured with a double-tag technique and predictions from the HERWIG 6.2 (*solid*), PYTHIA 6.156 (*dashed*), and ARIADNE 4.08 (*dotted*) event generators. The combined statistical (*inner bars*) and total uncertainty of the experimental data are shown. The *lower inset* shows the relative deviation of the models to the data. Also shown as the shaded area is the total one standard deviation relative uncertainty (statistical and systematic added in quadrature) of the data. Below $y_{cut} = 0.002$, the flavour tagging procedure fails and data results from the 1994 and 1995 data samples are not consistent with each other. **b** Comparison between the measured $R_4^{b\ell}$ and theoretical predictions: massive LO predictions and approximate (massless) NLO corrections for the pole and running b-quark mass definitions. Reference b-quark masses were obtained by evolving the average of low energy measurements $m_b(m_b) = 4.20 \pm 0.07$ GeV/c^2 [17] to the M_Z scale as explained in Sect. 4.5. Hadronisation corrections, used to correct ME calculations, are shown for the three generators in the *lower inset*

based on Poisson statistics. Central values were taken from the data and simulated samples, and correlations between the different quantities were accounted

for by building up the corresponding covariance matrix.

– *Gluon splitting*: The identification of primary b-quarks is based on the presence of long-lived B and D-hadrons in the final state. However, light-quark events with gluon radiation splitting into secondary heavy quarks can produce a similar signature. The correction procedure is very sensitive to the gluon splitting rates in the Monte Carlo simulation through the signal and background efficiencies [7]. Their value was varied in the range of their quoted uncertainties [26] and the observed change in the observables was added in quadrature and taken to represent the corresponding uncertainty.

– *Normalisation*: The uncertainty on the global normalisation R_b/R_ℓ is estimated by varying the world average values of R_b and $R_\ell = (1 - R_b - R_c)$ in the range of their quoted uncertainties [17], and taking the maximum variation in the final observable as the global normalisation uncertainty. This results in a 6‰ relative uncertainty and is y_{cut} independent. The uncertainty from the charm-/light-quark normalisation factor ($R_n^{c\ell} = R_n^c/R_n^\ell$) is estimated as half the maximum difference obtained by using as input to the measurement the prediction from the three event generators used: PYTHIA 6.156, HERWIG 6.2 and ARIADNE 4.08.

– *Flavour-tagging*: Signal efficiencies (ϵ_{nB}^b and ϵ_{nL}^{udsc}) are measured from data and therefore do not contribute to the total uncertainty for the double-tag technique. To estimate the uncertainty due to the imperfect description of background efficiencies and flavour correlations (ρ_{nQ}^q) in the simulation, the calibration of the b-tagging in the simulation was exchanged with the calibration obtained from data, which gives a poorer description of the lifetime probability [28]. Twice the observed difference was conservatively taken as the flavour-tagging uncertainty. For the event-tag technique, the related uncertainty was estimated as in [7] by varying the tagging efficiencies within their uncertainties: $\Delta\epsilon_{nB}^b/\epsilon_{nB}^b = 3\%$ and $\Delta\epsilon_{nL}^\ell/\epsilon_{nL}^\ell = 8\%$ evaluated in reference [28]. The effect of mistagging efficiency was estimated by considering light-tagging as equivalent to anti b-tagging, i.e. $\Delta\epsilon_{n\ell}^q = \Delta\epsilon_{nb}^q$ for $q = b, c, \ell$ for the same cut value.

4.4 Hadronisation corrections

To compare parton-level fixed order ME calculations of $R_4^{b\ell-\mathrm{part}}$ with experimental results, they must be corrected for hadronisation effects:

$$R_4^{b\ell} = H_4^{b\ell} R_4^{b\ell-\mathrm{part}} . \qquad (9)$$

The corrections $H_4^{b\ell}(y_{cut})$ relating parton to hadron observables are taken to be linear bin-to-bin factors.

Three different generators, each tuned independently to the DELPHI data [24, 25], were used in this analysis: PYTHIA 6.156, HERWIG 6.2 and ARIADNE 4.08. It was found that the HERWIG and ARIADNE event

generators are consistent both with the theoretical predictions at the parton level (within the theoretical uncertainty) and the data (see Fig. 4) for a large range of y_{cut}. The hadronisation corrections computed with the three generators are shown in Fig. 4b. The average of the HERWIG and ARIADNE predictions was used to correct the massive ME theoretical calculations (in the region of y_{cut} studied here, the hadronisation correction computed from PYTHIA is contained in the band defined by the HERWIG and ARIADNE corrections).

4.5 b-quark mass extraction and approximate NLO ME calculation

For a given flavour q, the n-jet rate is defined as the normalised n-jet cross-section $R_n^q = [\Gamma_n/\Gamma_{tot}]^{Z\to q\bar{q}}$. Theoretically, it is convenient to use the double-ratios $R_n^{b\ell} = R_n^b/R_n^\ell$ as in this observable most of the higher-order electroweak corrections, the first order dependence on α_s and, to some extent also neglected higher-order terms in α_s, cancel out. Massive ME theoretical calculations exist up to order α_s^2 [14–16] and describe the 2, 3 and 4-jet rates for heavy (b, c) and light quarks $(\ell = uds)$. Such calculations, when performed in the *on-shell* scheme in terms of the pole mass, M_q, can be rewritten in terms of the running mass, m_q, defined in the $\overline{MS}$ scheme, using the following order α_s relation:

$$M_q^2 = m_q^2(\mu) \left[1 + \frac{\alpha_s}{\pi} \left(\frac{8}{3} - 2\log\frac{m_q^2(\mu)}{\mu^2} \right) + \mathcal{O}\left(\alpha_s^2\right) \right] . \qquad (10)$$

Both mass definitions are equivalent at LO (see (10)). For $y_{cut} = 0.0065$, a value within a region with good stability, high sensitivity and small hadronisation corrections, the following b-quark mass value was obtained:

$$M_b = m_b(M_Z) = 3.76 \pm 0.32\,(\mathrm{stat}) \pm 0.17\,(\mathrm{syst})$$
$$\pm 0.22\,(\mathrm{had}) \pm 0.90\,(\mathrm{theo})\ \mathrm{GeV}/c^2 .$$

The theoretical uncertainty is estimated as half the difference between the $R_4^{b\ell}$ LO prediction for the running and pole b-quark mass definitions (see Fig. 4b).

To extract a meaningful b-quark running mass from the four-jet observable by means of (10), the NLO correction to R_n^q would be needed, which is only available for massless quarks [18–20]. However, an improvement of the LO estimation can be obtained if most of the mass effect is contained in the LO term and hence the NLO correction to $R_4^{b\ell}$ can be approximated as massless [21]:

$$R_4^{b\ell} = \frac{A^b(m_b)\alpha_s^2 + B^\ell\alpha_s^3}{A^\ell\alpha_s^2 + B^\ell\alpha_s^3} , \qquad (11)$$

where the LO functions A^b, A^ℓ are taken from [14–16] and the NLO massless term B^ℓ from [18–20]. As for the case of $R_3^{b\ell}$ [29], it was found that:

– The NLO corrections using the pole and running mass definitions were both within the uncertainty band defined by the two LO curves.
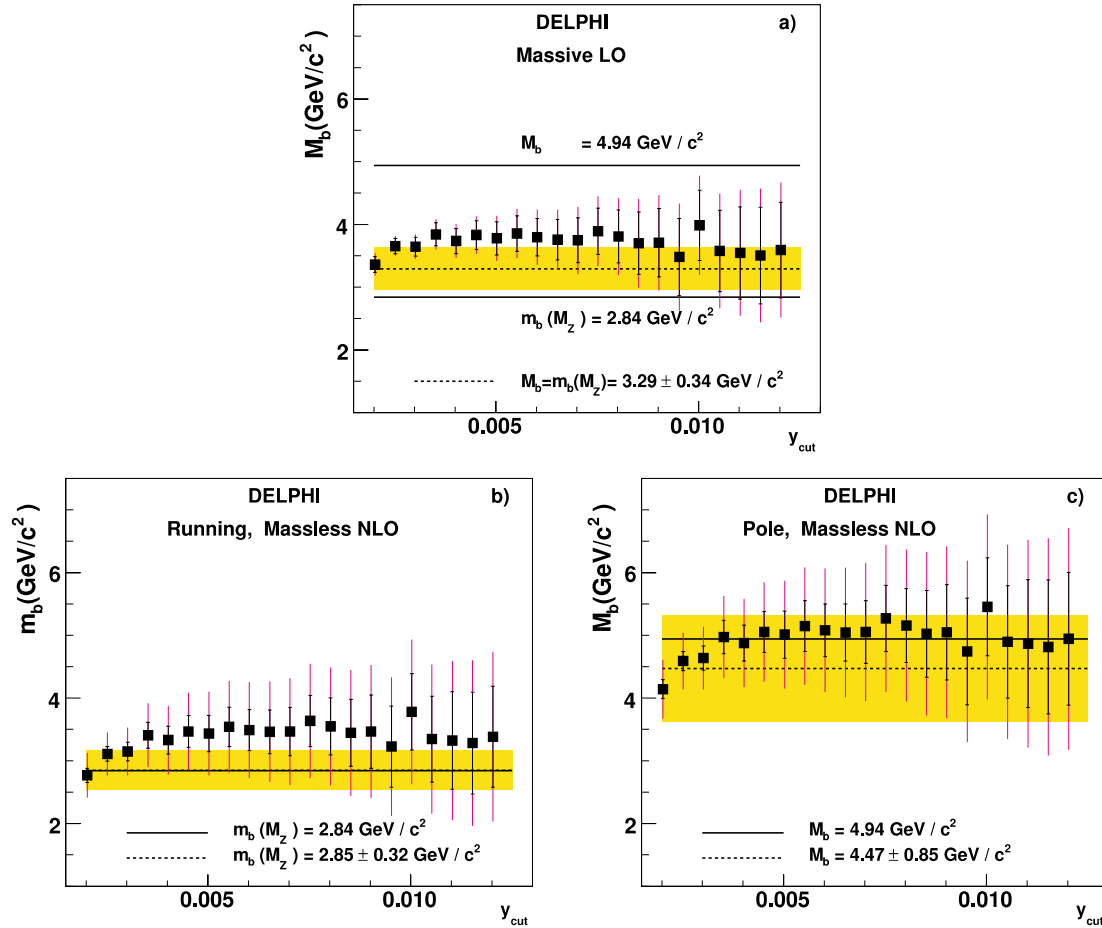

Fig. 5. a Massive LO results extracted from $R_4^{b\ell}$ (*data points*) compared with the result obtained at LO in the $R_3^{b\ell}$ analysis [7]: $M_b = m_b(M_Z) = 3.29 \pm 0.34 \, \text{GeV}/c^2$. In the LO result, no theoretical uncertainties are shown. Results obtained from $R_4^{b\ell}$ using massless NLO corrections include theoretical uncertainties estimated as explained in Sect. 4.5. They are shown for the **b** running and **c** pole mass definitions and are compared with the results obtained at NLO in the $R_3^{b\ell}$ analysis [7]: $m_b(M_Z) = 2.85 \pm 0.32 \, \text{GeV}/c^2$ and $M_b = 4.47 \pm 0.85 \, \text{GeV}/c^2$, respectively, shown as $\pm 1\sigma$ *shaded band* with its central value as a *dotted line*. Predicted values from the QCD calculations at low energy, described in Sect. 4.5, are also shown as *solid lines*

– The running mass definition results in a smaller correction at NLO than the pole mass.

The b-mass values obtained from $R_4^{b\ell}$ using this approximation are shown in Fig. 5b and c. They are found to be stable in the region $y_{\text{cut}} > 0.003$ and consistent with mass results obtained from $R_3^{b\ell}$ (both at LO and NLO) and predicted values from QCD calculations at low energy evolved to M_Z using the RGE. For the running mass calculation, the massless NLO correction is small and results in very little effect. On the contrary, for the pole mass the NLO correction is about 10%, leading to sizeable effects.

For the running b-quark mass definition, the theoretical prediction of $R_4^{b\ell}$ is taken to be the central value of the following, in principle equivalent, four calculations: (a) Full ratio as in (11), expressed in terms of the running mass by means of (10) at the scale $\mu = M_Z$; (b) Same, but using (10) at an arbitrary scale $\mu_0 = M_b$ and evolving the result to $\mu = M_Z$ via the RGE to obtain $m_b(M_Z)$; (c) Series expansion of (11), expressed in terms of $m_b(M_Z)$ as

in the first method; (d) Same, but introducing an arbitrary intermediate scale as in the second method. The pole mass prediction is obtained in a similar way. The resulting predictions for $R_4^{b\ell}$ are shown in Fig. 4b for a reference b-quark mass obtained by evolving the average of low energy measurements $m_b(m_b) = 4.20 \pm 0.07 \, \text{GeV}/c^2$ [17] to the M_Z scale, $m_b(M_Z) = 2.84 \pm 0.06 \, \text{GeV}/c^2$, or by translating it to a pole mass value: $M_b = 4.94 \pm 0.08 \, \text{GeV}/c^2$. The strong coupling constant value used was $\alpha_s(M_Z) = 0.1202 \pm 0.0050$ [30].

4.6 Theoretical and modelling uncertainties

The following sources of systematic uncertainty have been considered for the comparison of the corrected four-jet ME calculations with the experimental results:

– *Theoretical uncertainties*, due to missing higher orders in matrix element calculations and to the use of massless next-to-leading corrections for the mass extraction,

Table 6. Summary of experimental two and three-jet rates, with their total uncertainty, as a function of y_{cut} [8]

y_{cut}	R_2^b	R_2^ℓ	$R_2^{b\ell}$	R_3^b	R_3^ℓ
0.003	0.505 ± 0.003	0.481 ± 0.003	1.062 ± 0.004	0.342 ± 0.002	0.355 ± 0.003
0.004	0.553 ± 0.003	0.527 ± 0.003	1.060 ± 0.003	0.329 ± 0.002	0.345 ± 0.003
0.005	0.585 ± 0.003	0.562 ± 0.003	1.053 ± 0.003	0.317 ± 0.002	0.333 ± 0.003
0.006	0.611 ± 0.003	0.591 ± 0.003	1.046 ± 0.003	0.306 ± 0.003	0.321 ± 0.003
0.007	0.633 ± 0.003	0.615 ± 0.003	1.040 ± 0.003	0.295 ± 0.003	0.310 ± 0.003
0.008	0.651 ± 0.003	0.635 ± 0.003	1.040 ± 0.003	0.286 ± 0.002	0.300 ± 0.003
0.009	0.667 ± 0.003	0.653 ± 0.003	1.031 ± 0.003	0.277 ± 0.002	0.289 ± 0.003
0.010	0.681 ± 0.003	0.669 ± 0.004	1.027 ± 0.002	0.268 ± 0.002	0.280 ± 0.003

cannot be rigorously estimated in the case of four-jets. However, following a comparison between the same approximation applied to $R_3^{b\ell}$ with the full massive calculation available in this case, this uncertainty was conservatively taken to be twice the maximum difference between the four predictions defined in Sect. 4.5. The theoretical uncertainty is responsible for about 0.4–$0.5\,\mathrm{GeV}/c^2$ in the uncertainty of the final result, and it is almost independent of y_{cut}. Although lower than in the case of the LO calculation, it is three times higher than in the completely massive three-jet calculation.

- *Modelling uncertainties*, related to the correction for hadronisation effects of the theoretical calculations at parton level using Monte Carlo event generators. This includes the uncertainty on the tuned values of the free parameters in each model (including the b-mass parameter entering in the parton shower [7]) and the modelling of hadronisation. The size of the modelling uncertainty is estimated as half the difference between the predictions from HERWIG 6.2 and ARIADNE 4.08.[4] To include the b-mass uncertainty in the estimation of the hadronisation systematic uncertainty, the mass parameter in HERWIG and ARIADNE was varied within $\pm 0.125\,\mathrm{GeV}/c^2$ around their central values in order to maximize the difference between both predictions. This was achieved by setting the mass parameter to $M_b = 4.85\,\mathrm{GeV}/c^2$ in both generators. The total modelling uncertainty amounts to $\pm(1-2)\,\%$ in the region of $y_{\mathrm{cut}} > 0.004$, corresponding to about $\pm 0.2\,\mathrm{GeV}/c^2$ in terms of both the running and pole mass results. The contribution from varying the mass parameter amounts to about $\pm 0.1\,\mathrm{GeV}/c^2$.

The breakdown of the theoretical and modelling uncertainties in the b-quark mass results obtained from $R_4^{b\ell}$ is detailed in Table 5.

5 Summary and conclusions

A new determination of the hadron-level R_n^b and $R_n^{\ell=uds}$ jet-rates ($n = 2, 3, 4$ jets) has been performed, using flavour

tagging only in each n-jet sample and obtaining the global normalisation of the observables from the world average R_b and R_c measurements [17]. This measurement is based on a double-tag technique which measures the flavour-tagging efficiencies directly from data, thereby reducing systematic uncertainties.

Double-ratio observables are also studied: $R_4^{b\ell}$ is obtained from the four-jet rates R_4^b and R_4^ℓ using this double-tag technique, and $R_2^{b\ell}$ using the event-tag method defined in reference [7]. Results from $R_2^{b\ell}$ (and from the previous measurements of $R_3^{b\ell}$ in [7]) are also cross-checked.

Results are presented at hadron level, in order to allow for future comparisons without having to unfold hadronisation and detector corrections applied to the data (a summary of jet-rate results as a function of y_{cut} is shown in Tables 6 and 7). They are compared to three Monte Carlo event generators: PYTHIA 6.156, HERWIG 6.2 and ARIADNE 4.08, tuned to DELPHI data [24, 25]. The HERWIG 6.2 generator gives the best overall description of flavour jet-rates, R_n^b and R_n^ℓ, but ARIADNE 4.08 provides the best results for R_n^ℓ. For double-ratios, HERWIG 6.2 gives also the best description. However, the two-jet observable $R_2^{b\ell}$ is not satisfactorily described by any of the three generators considered.

A new determination of the b-quark mass in the four-jet topology has been performed using the CAMBRIDGE jet-clustering algorithm [8]. The mass is measured by comparing the experimental results of $R_4^{b\ell}$ at $y_{\mathrm{cut}} = 0.0065$ with fixed order ME massive LO calculations assuming the universality of the strong coupling constant, α_{s}. The measured

---

[4] The result obtained with the PYTHIA 6.156 event-generator is compatible with the quoted results within the modelling uncertainty.

Table 7. Summary of experimental four-jet rates, with their total uncertainty, as a function of y_{cut} [8]

y_{cut}	R_4^b	R_4^ℓ	$R_4^{b\ell}$
0.003	0.1148 ± 0.0013	0.1248 ± 0.0009	0.920 ± 0.013
0.004	0.0911 ± 0.0012	0.1018 ± 0.0007	0.895 ± 0.015
0.005	0.0757 ± 0.0012	0.0856 ± 0.0007	0.885 ± 0.016
0.006	0.0642 ± 0.0011	0.0729 ± 0.0007	0.882 ± 0.017
0.007	0.0555 ± 0.0010	0.0628 ± 0.0006	0.884 ± 0.019
0.008	0.0486 ± 0.0010	0.0551 ± 0.0006	0.88 ± 0.03
0.009	0.0432 ± 0.0010	0.0486 ± 0.0005	0.89 ± 0.02
0.010	0.0380 ± 0.0010	0.0431 ± 0.0005	0.88 ± 0.03

value is:

$$m_b(M_Z) = 3.76 \pm 0.32 \,(\text{stat}) \pm 0.17 \,(\text{syst}) \pm 0.22 \,(\text{had})$$
$$\pm \, 0.90 \,(\text{theo}) \,\text{GeV}/c^2 \, .$$

A procedure to approximate the NLO corrections with the massless component in order to improve the result has been tested successfully with the three-jet massive calculations. The measured value of the running b-quark mass when applying this method to the four-jet observable is:

$$m_b(M_Z) = 3.46 \pm 0.35 \,(\text{stat}) \pm 0.19 \,(\text{syst}) \pm 0.24 \,(\text{mod})$$
$$\pm \, 0.44 \,(\text{theo}) \,\text{GeV}/c^2$$

and the corresponding value for the pole mass is:

$$M_b = 5.07 \pm 0.46 \,(\text{stat}) \pm 0.24 \,(\text{syst}) \pm 0.32 \,(\text{mod})$$
$$\pm \, 0.57 \,(\text{theo}) \,\text{GeV}/c^2 \, .$$

These results agree within the uncertainties with the values obtained evolving the average of low energy measurements $m_b(m_b) = 4.20 \pm 0.07 \,\text{GeV}/c^2$ [17] to the M_Z scale using the RGE: $m_b(M_Z) = 2.84 \pm 0.06 \,\text{GeV}/c^2$, or by translating it to a pole mass value: $M_b = 4.94 \pm 0.08 \,\text{GeV}/c^2$. The values of $m_b(M_Z)$ obtained from the LO and approximate NLO $R_4^{b\ell}$ calculations are shown in Fig. 6 together with results from other measurements at the M_Z scale, in particular the most precise result from $R_3^{b\ell}$, $m_b(M_Z) = 2.85 \pm$

Fig. 6. The energy evolution of the $\overline{MS}$-running b-quark mass $m_b(Q)$ as measured at LEP. DELPHI results from $R_3^{b\ell}$ [7] at the M_Z scale and from semileptonic B-decays [31] at low energy are shown together with results from other experiments (ALEPH [4], OPAL [5] and SLD [6]). The masses extracted from LO and approximate NLO calculations of $R_4^{b\ell}$ are found to be consistent with previous experimental results and with the reference value $m_b(Q)$ (*grey band*) obtained from evolving the average $m_b(m_b) = 4.20 \pm 0.07 \,\text{GeV}/c^2$ from [17] using QCD RGE (with a strong coupling constant value $\alpha_s(M_Z) = 0.1202 \pm 0.0050$ [30])

$0.32 \,\text{GeV}/c^2$ [7], as well as results at low energy from semileptonic B-decays [31] obtained at a lower mass scale. All experimental results are consistent with each other assuming the QCD running prediction from RGE.

The main limitation in the extraction of $m_b(M_Z)$ from the $R_4^{b\ell}$ measurement is theoretical. If a calculation with resummed LL logarithms [32, 33] could be used, a larger range of y_{cut} could be exploited. This could potentially lead to a lower uncertainty.

Improvements to the precision of $m_b(M_Z)$ are not expected from combining the different measurements because they are largely limited by common systematic uncertainties. Other methods will likely be needed at future colliders in order to obtain more precise determinations of the b-quark mass at high energy. This will be important to interpret the precise measurements at the Linear Collider in searches for new physics. As an example, a future linear collider operating at $\sqrt{s} = 500 \,\text{GeV}$ will produce Higgs bosons copiously (if they exist). Since the decay branching fraction into b-quarks is expected to be proportional to the mass squared, measurements of this decay channel would be very sensitive to the exact value of the mass at that scale.
